Consider the following differential equation with an embedded optimization problem (DAEO):

$$\begin{aligned}x(0) &= 1 \\ \dot{x}(t) &= y^*(t) \\ \{y^k(t)\} &= \arg \min_y h(x, y) \\ h(x, y) &= (x - y)^2 + \sin 5y\end{aligned}\tag{1}$$

How might we approach solving this equation numerically?

The circular dependence of $x(t)$ on the solution to the minimization problem $y(t)$ poses an issue. We could try separating the two problems, and solving the optimization problem between each time step:

$$\begin{aligned} y^{k\star} &= \arg \min_y h(x^k, y) \\ x^{k+1} &= x^k + \frac{\Delta t}{2} (f(x^k, y^{k\star}) + f(x^{k+1}, y^{k\star})) \end{aligned} \tag{2}$$

This approach has two problems:

- ▶ Global optimization is, especially for larger problems, is very expensive.
- ▶ What happens when the global optimizer y^* changes between two times t^k, t^{k+1} ?

- ▶ $\{y_i\}$ is the set of minimizers of $h(x, y)$
- ▶ y^* is the global minimizer of h
- ▶ $\nabla_y f$ is the gradient of f w.r.t. y
- ▶ $\partial_y f$ and $d_y f$ are partial and total derivatives, respectively.
- ▶ Δt is the time step size.
- ▶ x^k is the value of x at time step t^k
- ▶ y_i^k is the value of y_i at time step t^k

Without some way to detect a global optimizer change during a time step, any integration method we choose for $x(t)$ will have its order of convergence *reduced to 1*³!

In order to solve this problem, we'll first need a global optimizer that can find *all* local optimizers of $h(x, y)$.

Fundamental Theorem of Interval Arithmetic¹

An interval evaluation of a function $[y] = [\underline{y}, \bar{y}] = f([\underline{x}, \bar{x}]) = f([x])$ must yield an interval that contains all pointwise evaluations $f(x) \forall x \in [\underline{x}, \bar{x}]$.

In the world of floating-point numbers, **IEEE 1788-2015** specifies basic interval arithmetic (IA). The Boost interval library⁴ follows this standard.

If we had access to *interval gradients*, this process would be much easier...

Consider some function f , and its tangent- and adjoint-mode evaluations:

$$y = f(x): \mathbb{R}^n \mapsto \mathbb{R}^m$$

$$y^{(1)} = \nabla_x f(x) \cdot x^{(1)}$$

$$x_{(1)} = y_{(1)} \cdot \nabla_x f(x)$$

With a suitable AD tool (perhaps dco/c++²), we could substitute intervals directly into tangent- and adjoint-mode AD.

An interval evaluation of the tangent of f must yield a correct interval for $y^{(1)}$:

$$[y^{(1)}] = \nabla_x f([x]) \cdot x^{(1)}$$

An interval evaluation of the adjoint of f must yield a correct interval for $x_{(1)}$:

$$[x_{(1)}] = y_{(1)} \cdot \nabla_x f([x])$$

Testing if an interval $[\underline{x}, \bar{x}]$ contains a critical point is quite straightforward.

First-Order Optimality with Intervals

The interval $[x]$ contains a critical point if $0 \in [\nabla_x f_i]$.

Second-order optimality is a bit more difficult. We can compute the interval Hessian $[H_x f]$ via AD exactly as we would compute the regular Hessian.

Second-Order Optimality with Intervals

The interval $[x]$ contains exactly one minimum of f if, for every matrix $A \in [H_x f([x])]$, A is positive definite.

Branch-and-Act with Interval Arithmetic

Process the list of intervals to search for optimizers $\mathfrak{S} = \{[y]\}$ according to the following rules:

1. Take the first item $[y]$ from \mathfrak{S} .
2. **Gradient Test:** Evaluate the interval gradient $\partial_y h(x, [y])$. If the result interval does not contain 0, $[y]$ contains no optimizers and can be discarded.
3. **Hessian Test:** Test the interval Hessian $\partial_y^2 h(x, [y])$ for positive definite-ness.
 - 3.1 If the interval Hessian is negative definite, h is concave down over the interval $[y]$, and $[y]$ can be discarded.
 - 3.2 If the interval Hessian is positive definite, h is concave up over the interval $[y]$, and $[y]$ can be narrowed by any appropriate local optimization method.
4. **Branch:** If the interval Hessian is neither positive- nor negative definite, decompose the interval $[y]$ and append the results to \mathfrak{S} .
5. Repeat for all remaining items in \mathfrak{S} .

The reason that the initial integration strategy fails is because of "events".

An event occurs at some time $\tau \geq t_0$, when there is a $y^i(\tau) \neq y^*(\tau) \in \{y_k(\tau)\}$ such that

$$h(x(\tau), y^*(\tau)) = h(x(\tau), y^i(\tau)) \quad (3)$$

Two scenarios can lead to an event:

- ▶ The global optimizer shifts from $y^i(t)$ to $y^j(t)$ as the system evolves.
- ▶ The global optimizer is both $y^i(\tau)$ and $y^j(\tau)$ *only* at $t = \tau$.

We can test if a time step from t_k to t_{k+1} contained an event between any two local optimizers y^i and y^j by testing for a sign change in the *event function*

$$H(x^k, y^i, y^j) = h(x^k, y^i) - h(x^k, y^j) \quad (4)$$

In time steps where this situation occurs, a root-finding procedure can find the time τ where $H(x^k, y^i, y^j) = 0$, and the time stepping procedure for (1) can step from t_k to τ to t_{k+1} .

Local Optimizer Drift Estimate

$$0 = \partial_y h(x, y_i)$$

$$0 = d_x \partial_y h(x, y_i)$$

$$0 = \partial_{yy}^2 h(x, y_i) \cdot \partial_x y_i + \partial_{xy}^2 h(x, y_i) \quad (5)$$

$$\partial_x y_i = - \left(\partial_{yy}^2 h(x, y_i) \right)^{-1} \partial_{xy}^2 h(x, y_i)$$

$$\partial_t y_i = - \left(\partial_{yy}^2 h(x, y_i) \right)^{-1} \partial_{xy}^2 h(x, y_i) f(x, y_i)$$

An Integrator for DAEs

Time stepping:

$$\begin{aligned} 0 &= x^k - x^{k+1} + \frac{\Delta t}{2} (f(x^k, y^{*,n}) + f(x^{k+1}, y^{*,k+1})) \\ 0 &= \partial_{y_i} h(x^{k+1}, y_i^{k+1}) \end{aligned} \tag{6}$$

In practice, a suitable guess for x^{k+1} and y_i^{k+1} is

$$\begin{aligned} x^{k+1} &= x^k + f(x^k, y^{*,k}) \Delta t \\ y_i^{k+1} &= y_i^k + \partial_{y_i} h(x^k, y_i^k) \Delta t \end{aligned}$$

- ▶ We have successfully restored the 2nd-order convergence of an implicit Euler scheme.
- ▶ We avoid expensive global optimizer calls during the integration of a DAEO.

For all the juicy details...

`STCE-at-RWTH/daeo-tracking-solver`

The current state of the project leads to some natural next steps:

- ▶ Can we quantify the quality of an estimate for the local optimizer drift?
- ▶ How should we compute derivatives w.r.t. y near events?
- ▶ Is it possible to include second-order information in the time stepping for $\{y_i\}$?
- ▶ What are the best choices for hyper-parameters (Event detection threshold, estimates for Lipschitz constants)?

The global optimizer component could also be very much improved.

- ▶ How should we perform global optimization under constraints?
- ▶ Is there a better way to test interval matrices for positive-definiteness?
